ABSTRACT

A three-dimensional acoustic Luneburg meta-lens has the advantage of refracting sound waves for all incident angles and focusing higher sound pressure compared to a two-dimensional lens. The lens made of plastic with a diameter of 120 mm was designed with thousands of lattice column-shaped meta-atoms to maintain its three-dimensional shape. The lens's three-dimensional focusing performance and acoustic imaging were simulated and measured in the frequency range of 5 kHz–20 kHz. The omnidirectional property was confirmed by rotating the lens to change the incident angle and measuring the sound pressure. The development of these spherical Luneburg meta-lenses is expected to improve the performance of devices that require acoustic focusing.

Published under license by AIP Publishing. <https://doi.org/10.1063/5.0037600>

The Luneburg lens, which was proposed as a model of the wave transformation theory by Luneburg in the 1940s, is a type of gradient index (GRIN) lens that can focus incoming waves on the opposite side of the lens without aberration.¹ Some theoretical and experimental validation of the lens was conducted in the 1960s,^{2,3} and the lenses with metamaterial structures were realized in various methods and shapes in the 21st century.^{4–7} Its high gain and spherical symmetry advantages, design optimization,^{8,9} printed circuit board fabrication technique,^{10,11} quasi-conformal transformation optics,¹² and metamaterial structures^{13–16} were used to apply the lenses to antennas. These studies have been mainly conducted in the electromagnetic and optical fields, but attempts have also been made to apply them to sound waves.

With the advent of metamaterials, research on the implementation of acoustic focusing^{17–23} was conducted to overcome the limitations of existing materials by controlling the waves, and the Luneburg lens was no exception. Kim realized the performance of a two-dimensional (2D) acoustic Luneburg meta-lens in the audible frequency range.^{24,25} Moreover, many methods and shapes have been proposed to achieve this. An acoustic Luneburg lens composed of orifice-type unit cells²⁶ and a 2D flattened lens designed using a quasi-conformal mapping method^{27,28} has been presented. Anisotropic acoustic Luneburg lenses such as Luneburg-fisheye combined²⁹ and Luneburg retroreflector³⁰ were introduced.

Research on the acoustic Luneburg meta-lenses has expanded to a three-dimensional (3D) shape because the 3D lenses have the advantage of focusing incident waves in all directions and achieving a higher sound pressure level (SPL) than the 2D lenses. Fabricated 2D and 3D lenses and the performance of the 2D lens in the ultrasound frequency range were studied by Xie *et al.*³¹ After that, Zhao *et al.* reported ultrasound beam steering using 2D and 3D flattened acoustic metamaterial Luneburg lenses at 40 kHz.³² Despite these pioneering studies, frequency-dependent focusing performance and acoustic imaging, consistent with 3D numerical simulation and experimental results for full 3D lenses, have not been reported.

In this paper, a 3D acoustic Luneburg meta-lens, or an acoustic Luneburg ball, composed of lattice column-shaped meta-atoms to maintain its three-dimensional shape was designed and fabricated, and its focusing performance was confirmed using COMSOL Multiphysics. Acoustic imaging was measured in the frequency range of 5 kHz–20 kHz using a transducer, microphone, three-axis linear stage, and control module. It was then demonstrated to have the omnidirectional property by rotating the lens to change the incident angle and measuring the sound pressure around the lens.

The refractive index (RI) formula of the Luneburg lens is $n(r) = n_0 \sqrt{2 - (r/R)^2}$, where n_0 is the RI of the surrounding

FIG. 1. Refractive index and structure of the 3D acoustic Luneburg meta-lens. (a) Refractive index n by the radius of each layer r . (b) Luneburg ball and its lattice column unit cells. (c) Ratio δ_i and (d) frequency-dependent effective refractive index n_{eff} .

medium, R is the radius of the lens, and r is the distance from the center of the lens. It is possible to discretize the volume as many concentric layers due to the spherical symmetry. If the lens is divided into N layers, the RI is newly defined as

$$n(i) = \sqrt{2 - \left(\frac{i}{N}\right)^2}, \quad (1)$$

where $i = 0, 1, 2, \dots, (N-1)$ and $N = 10$ is chosen in the design. The lattice columns' sizes increase toward the center of the lens, and the RI changes for each layer, as shown in Fig. 1(a). α_i and β are the dimensions of the meta-atoms and unit cells. The radius of the lens R is 60 mm, and the length of the unit cell β is 6 mm. α_i is the length of one side of the i th meta-atoms and varies depending on each layers' position. Therefore, the ratio is set to $0 < \delta_i = \alpha_i/\beta < 1$. It can be seen that the RI is derived as $n(\delta_i) = 1/\sqrt{1 - 3\delta_i^2 + 2\delta_i^3}$ and the index varies according to the size of the meta-atoms in Fig. 1(a). The lens is designed in a form in which 19 layers are stacked while maintaining the 3D shape in Fig. 1(b).

The index was also calculated to retrieve effective material properties of the acoustic metamaterials. It was simulated to obtain the reflection R and transmission coefficients T using COMSOL Multiphysics, a finite element analysis. The formulas for the effective refractive index n_{eff} and acoustic impedance ζ derived from the retrieval method are as follows:³³

$$n_{eff} = \frac{1}{kd} \left\{ 2\pi m \pm \cos^{-1} \left(\frac{1 - (R^2 - T^2)}{2T} \right) \right\}, \quad (2)$$

$$\zeta = \pm \sqrt{\frac{(1 + R)^2 - T^2}{(1 - R)^2 - T^2}}, \quad (3)$$

where k is the wavenumber, d is the slab thickness, and m is the branch number of $\cos^{-1}$ function. The relationships between the effective refractive index and ratio and the frequency-dependent index are

plotted in Figs. 1(c) and 1(d). It was shown that the index does not gradually change above 18 kHz. Therefore, the lens has a frequency-dependent property, and the focusing performance depends on the frequency. From the two figures, it can be predicted that the applicable frequency range is up to approximately 17 kHz.

The simulated focusing performance of the polyamide plastic lens ($\rho = 1000 \text{ kg/m}^3$ and $c = 2200 \text{ m/s}$) in the air ($\rho = 1.2 \text{ kg/m}^3$ and $c = 343 \text{ m/s}$) is shown in Fig. 2 expressed as sound pressure. The acoustics module was used in the frequency domain, solving the Helmholtz equation to analyze its acoustics effects and check the performance by frequency. As a result of the simulation, the sound waves are focused from 5 to 15 kHz, but not at 20 kHz. In general, the size of the unit cell is a subwavelength dimension, so that the lens does not work at the frequency of 20 kHz ($\lambda/4 = 4.875 \text{ mm}$). In addition, this reason can also be confirmed in Figs. 1(c) and 1(d). Therefore, the simulation and applicable frequency range of the lens matches.

The lens was fabricated using a selective-laser-sintering 3D printer. The experimental setup was configured to validate the performance of the fabricated lens in Fig. 3. The reflection of sound waves was minimized by surrounding the measurement space with a sound-absorbing material. The supporter was connected to the plastic structure so that the lens is completely fixed to the bottom. When sound waves move from the transducer to the lens, the sound pressure was measured around the lens while moving in the three-axis direction of a microphone connected to the three-axis linear stage. The transducer

generated acoustic pulse signals, which had a signal amplitude of 2 V, a burst count of 25, a burst period of 50 ms, and a wait time of 500 ms. The pressure was measured while rotating the lens (10° , 20° , 30° , and 40°) to demonstrate the omnidirectional property. Acoustic imaging

FIG. 5. Experimental results of acoustic imaging at a frequency of 10 kHz. (a)–(e) Acoustic imaging in the yz-plane with the incident angles of 0°, 10°, 20°, 30°, and 40°. (f)–(j) Acoustic imaging in the xy-plane with the incident angles of 0°, 10°, 20°, 30°, and 40°. These results are normalized intensity data.

was measured by scanning the yz- ($140 \times 140 \text{ mm}^2$) and xy-planes ($70 \times 140 \text{ mm}^2$) of the lens's output area by a step size of 1 mm. The SPL ($L_p = 20 \log(p/p_o)$, p ; sound pressure, $p_o = 20 \text{ } \mu\text{Pa}$; and reference sound pressure in the air) recorded in the LabVIEW PC has been converted to the intensity ($I = p^2/Z_0$, $Z_0 = 411.6 \text{ rayl}$; and specific acoustic impedance in the air) to represent the full width at half maximum (FWHM) and focal length.

The rotational symmetry is shown in Fig. 4(a) expressed as normalized intensity. The comparison between numerical simulation and measurement results at a frequency of 10 kHz in the y- and x-axis is shown in Figs. 4(b) and 4(c), respectively. The FWHM is approximately 16.426 mm ($= 0.479\lambda$), and the focal lengths are 78 mm ($F/R = 1.3$) and 65 mm ($F/R = 1.1$) in the simulation and measurement, respectively. In principle, the focusing should be perfect ($F/R = 1$); however, it is a bit broad. This is because the refractive indices of the ideal, designed, and fabricated lenses are different due to discretization into several layers and fabrication errors. As a result, the focal length is larger than the radius of the lens. Therefore, the focal point is formed exterior to the lens and not the interior.^{34,35} Acoustic imaging expressed as normalized intensity for the yz- and xy-planes at a frequency of 10 kHz is plotted in Fig. 5. The rotational symmetry was confirmed in the yz-plane [Figs. 5(a)–5(e)] and in the xy-plane [Figs. 5(f)–5(j)].

The design, simulation, fabrication, and measurement of the 3D acoustic Luneburg meta-lens with a diameter of 120 mm were studied. The meta-atoms were designed as lattice columns to realize a 3D lens discretized into 10 layers. The frequency-dependent focusing performance was verified through the retrieval method and numerical simulation. Its omnidirectional property was confirmed by changing the incident angle while rotating the lens. The applicable frequency range was 5–17 kHz. Acoustic imaging was measured in the yz- and xy-planes at a frequency of 10 kHz. These focusing and beam steering functions can detect weak signals from all directions or increase imaging performance. Therefore, this makes them suitable for sensing applications such as acoustic imaging systems, acoustic communication, nondestructive testing, and energy harvesting.^{36–40}
